ABSTRACT

Species distributions models (SDMs) are commonly used to assess potential species' range shifts or extinction risk under climate change. It has been suggested that the use of ensemble forecasts, where a variety of model algorithms are used to generate consensus predictions, are preferred to individual SDMs by avoiding bias or prediction error inherent in a single modeling approach. Whereas several studies have assessed the performance of ensemble predictions using cross-validation or data-partitioning approaches, few studies have assessed the predictive accuracy of ensemble forecasts under climate change by using temporally independent model validation data. We used five SDM approaches to develop consensus forecasts of distributions of 145 vascular plant species from California in the 1930s and tested their projections against current distributions, a span of approximately 75 years. When evaluated with a portion of the model training data, consensus forecasts were highly accurate with an average AUC value of 0.97. False positive and false negative error rates were also low, exhibiting similar performance to random forest models. However, when evaluated with temporally independent data, the accuracy of consensus forecasts was similar to that of generalized linear and generalized additive models, with an average AUC value of 0.83. Our results suggest that the high levels of predictive accuracy exhibited by consensus forecasts when using data partitioning approaches may not reflect their performance when predicting temporally independent data. We contend that consensus forecasts may not represent the best approach for predicting species distributions under future climatic change, as they may not provide superior predictive accuracy in novel temporal domains compared to traditional modeling approaches that more readily lend themselves to ecological interpretation of model structure.

1. Introduction

In recent years, the increasing availability of spatially explicit climate and species distribution data has led to the widespread use of species distribution models (SDMs) in ecological research. These models are often used to predict the impacts of climate change on biota by relating current species distributions to climate and then projecting future distributions under various climate change scenarios (Elith and Leathwick, 2009). There are now a variety of statistical techniques used to develop SDMs (Elith et al., 2006), although most studies continue to use a single modeling approach (Hanspach et al., 2010). Previous studies have advocated for the use of a single modeling algorithm, often suggesting that a single method may be superior (Lehman and Overton, 2002). However, recent studies comparing the accuracy of various modeling approaches

have shown that prediction accuracy can vary substantially among modeling algorithms and have consistently failed to identify any single modeling approach as being superior to others (Segurado and Araújo, 2004; Elith et al., 2006; Pearson et al., 2006). Although these studies typically use data from a single time period to develop and test their models, there is also evidence to suggest that different modeling algorithms can lead to different predictions of species distributions over time (Araújo et al., 2005a; Dobrowski et al., 2011).

Because of this model based uncertainty in SDM accuracy, it has been suggested that the use of individual modeling algorithms should be abandoned in favor of ensemble forecasts (Araújo and New, 2007). The general premise behind ensembles is that uncertainty in individual model forecasts can be reduced by simultaneously considering the results from multiple models. This approach assumes that when averaging across multiple models that the true "signal" of interest will separate itself from the "noise" and bias associated with any individual models (Araújo and New, 2007). Recent studies have shown that consensus modeling methods may improve SDM predictions compared to individual modeling algorithms (Crossman and Bass, 2008; Marmion et al., 2009). As with the previous studies of SDM performance mentioned

above, these works have used data within a single time frame to both develop and test models (Grenouillet et al., 2011). Conversely, recent studies using data from multiple time frames have shown inconsistent results with regards to ensemble forecast accuracy (Rapacciuolo et al., 2012; Smith et al., 2013). Because the factors affecting SDM accuracy within a single time frame may differ from those conferring accuracy when predicting into a novel time frame for individual modeling algorithms, evaluations of consensus forecasts across time are warranted.

It has been suggested that using data from two time periods represents the only way to directly assess the performance of SDMs for predicting climate change impacts (Nogues-Bravo, 2009). However, such data are extremely rare and, as such, there have been comparatively few instances of such data being used in evaluations of consensus forecasts. In one of the first studies to use such datasets, (Araújo et al., 2005b) found that consensus forecasts yielded more accurate predictions of coarse-resolution changes in bird species range size than individual (non-consensus) models, although the spatial resolution of their study limited the applicability of their results. However, more recent studies have presented conflicting evidence regarding how ensemble forecasts will compare to individual algorithms when projecting distributions across time, with some evidence suggesting ensembles provide superior prediction accuracy (Rapacciuolo et al., 2012) while other research suggests they do not (Smith et al., 2013). The objectives of this study were to (1) test whether consensus forecasts yield more accurate predictions of plant species distributions under climate change than individual models, and (2) determine if measures of consensus forecast accuracy based on data from a single time frame correlate to measures of accuracy in a novel time frame.

2. Materials and methods

2.1. Study area

Our study area comprised the dominant mountain ranges of California, USA, an area of approximately 220,000 km². This area was ideal for assessing climate change impacts on species distributions as it covered major biophysical gradients and has experienced substantial and diverse climate change during the 20th century which has led to major shifts in plant species distributions (Crimmins et al., 2011).

2.2. Vegetation data

We used plant species presence and absence data from two time periods to develop and test ensemble forecasts. We used historical species presence and absence data from 13,746 plots collected between 1928 and 1940 as part of the Vegetation Type Map Project (VTM) (Wieslander, 1935a,b). Georeferenced plot locations were estimated to be accurate within 200 m (Kelly et al., 2005). We compiled a collection of 33,596 contemporary vegetation plots from a variety of sources including the US Forest Service, National Park Service, California Fish and Game, US Geological Survey, California Native Plant Society, and academic institutions. All plots were georeferenced with similar accuracy to our historical data. From both datasets we extracted presence and absence locations for 145 plant species with sufficient representation in both time periods (≥ 30 occurrences).

2.3. Climate data

We developed a parsimonious suite of four climatic predictor variables that we hypothesized would exhibit direct influence on species distributions and displayed low levels of correlation

($r < 0.6$). We used gridded 800-m resolution climate data from two time periods approximately representing 30-year time frames prior to vegetation data collection (1906–1935, 1976–2005). We used two climatic variables from the parameter-elevation regression on Independent Slopes Model (PRISM) (Daly et al., 2008) dataset, maximum temperature and minimum temperature. We also used two hydrologic variables that have been shown both theoretically and empirically to affect vascular plant distributions: mean annual actual evapotranspiration, and mean annual climatic water deficit (Stephenson, 1990, 1998). The hydrologic variables were developed using a modified climatic water balance model (Lutz et al., 2010) that accounts for snowmelt and soil moisture storage (Dobrowski et al., 2013).

2.4. Species distribution models

We used five widely applied statistical methods to model plant species distributions. These included two regression techniques (generalized linear models, GLM; generalized additive models, GAM), two machine learning techniques (generalized boosting machines, GBM; random forest, RF), and one classification technique (classification trees; CT). These techniques have been widely used in species distribution modeling applications, represent a broad range of analytical approaches, and were used in a recent study that concluded consensus forecasts yielded very accurate predictions of species distributions for climate change impact studies (Marmion et al., 2009). We built and calibrated models using a randomly selected 75% of the historical data. We tested the accuracy of predicted species distributions using the withheld 25% of the original data (internal evaluation) and using 100% of the contemporary data (independent evaluation). We computed model accuracy using the area under the curve (AUC) statistic (Fielding and Bell, 1997). Because AUC is often considered inadequate for assessing species distribution model performance (Lobo et al., 2008) we also converted probability of occurrence values into binary presence–absence predictions using the sensitivity–specificity equality approach to select prediction thresholds for each model (Cantor et al., 1999). Using these binary predictions we calculated false positive (FP) and false negative (FN) fractions. Although our FP and FN fractions may be biased due to mismatch in spatial resolution between our vegetation and climate data, we assumed such bias was minimal.

2.5. Consensus forecasts

We use the term “consensus forecast” to mean a single prediction that represents a measure of central tendency across a suite of individual models (Araújo et al., 2005b). In our case we chose to use the average predicted probability of occurrence across the five models as our consensus forecast. This is analogous to the Mean(all) approach used by Marmion et al. (2009), which they suggested was one of the best methods for developing consensus predictions. These predictions were evaluated using AUC and threshold dependent FP and FN fractions as described above. Prediction accuracy metrics between individual models and consensus forecasts were evaluated using paired *t*-tests to control for species effects. Variances of accuracy metrics between modeling approaches were compared using *F*-tests.

3. Results

Spatial patterns in predicted probability of occurrence varied among model algorithms and between time periods (see Fig. 1). When using internal evaluations, consensus forecasts had high mean AUC values across our 145 study species ($\bar{x} = 0.97$) that exceeded AUC values for all individual model algorithms except for

Fig. 1. Example of differences in spatial patterns of predicted probability of occurrence between selected model algorithms in two independent time periods in California, USA. Predictions shown are for models of *Purshia tridentata* occurrence developed using historical (1906–1935) data. Lighter areas represent higher probabilities.

the RF model ($P < 0.05$, Fig. 2). AUC values for consensus forecasts were also less variable than those for individual model algorithms except for the RF models ($P < 0.05$, Fig. 2). Consensus forecasts had lower mean false positive error rates and variance in error rates when using internal evaluations than any individual model algorithm ($P < 0.05$, Fig. 2). Consensus forecasts also had lower mean false negative error rates and variance in error rates than any individual model algorithm except for the RF models (Fig. 2).

When evaluated with temporally independent data, AUC values for consensus forecasts dropped to 0.833, which was not significantly better than our GLM ($\bar{x} = 0.829$) or GAM ($\bar{x} = 0.835$) forecasts (Fig. 2). Mean false positive error rates from consensus forecasts of temporally independent data were statistically lower than individual model algorithms, although the magnitude of these differences was small compared to GAM and GBM forecasts (Fig. 2). Mean false negative error rates from consensus forecasts of temporally independent data were significantly higher ($P < 0.05$) than all individual model algorithms except for the GBM forecasts (Fig. 2). Variability in false positive error rates from consensus forecasts were significantly lower than from any individual model algorithm, while variability in false negative error rates from consensus forecasts were significantly lower than for any individual model algorithm except for GLM (Fig. 2).

4. Discussion

Many authors have promoted the use of ensemble forecasts for predicting species distributions under future climate scenarios (Araújo and New, 2007; Buisson et al., 2010). The primary

motivation behind the use of ensembles is that previous research has shown that predictions of species distributions can vary widely among modeling approaches, and thus ensembles can avoid any pitfalls associated with a single modeling approach, and that using multiple algorithms can improve the ability of researchers to detect true ecological signal from the “noise” associated with individual model uncertainties (Araújo and New, 2007). Thus, the use of ensembles should alleviate problems associated with individual models inaccurately predicting species occurrence at individual locations by focusing on central tendency. It has also been suggested that ensembles can improve the accuracy of species distribution forecasts (Marmion et al., 2009). However, these studies suffer from two fundamental flaws in the context of predicting species distributions through time. The first is that these recommendations are often based on evaluations of prediction precision (i.e. agreement) among modeling approaches rather than actual prediction accuracy (Buisson et al., 2010). The second is that, when actual model accuracy is evaluated, such studies have not used temporally independent data to validate their projections, and thus conclusions of improved accuracy are based solely on data partitioning approaches (Marmion et al., 2009) which may not always accurately reflect model performance in novel temporal domains (Dobrowski et al., 2011). Because previous studies promoting the use of ensembles have incorrectly considered precision among models as a measure of accuracy, it has been suggested that assumptions associated with the use of ensembles may limit their utility for informing conservation management (Schwartz, 2012). Here, we show predictions of future plant species distributions from one such ensemble classifier are not more accurate than

Fig. 2. Boxplots of mean ($n = 145$ species) accuracy metrics for five individual SDMs and one consensus forecast using internal and independent evaluation data.

those from several individual modeling algorithms, consistent with a recent study of mammalian distributions (Smith et al., 2013). Furthermore, the variability in projection accuracy of our ensemble was not substantially lower than that from several of the individual model algorithms (Fig. 2), indicating that in some

cases ensemble forecasts may not be more useful than individual modeling approaches.

Ensemble forecasts can be developed in numerous ways (Marmion et al., 2009), and our approach of averaging predictions from individual algorithms is arguably the most simplistic.

However, studies using data partitioning approaches (Marmion et al., 2009) and temporally independent data (Rapacciuolo et al., 2012) have found that this approach provided significant improvements to model accuracy and suggested that it may provide the most accurate predictions among various ensemble approaches. Our internal evaluations yielded similar results, with very high levels of model accuracy even when compared to other relatively complex individual modeling approaches. However, our independent evaluations indicated that consensus forecasts did little to improve model projections compared to more traditional modeling approaches such as GLM or GAM. Aside from providing similar levels of prediction accuracy in our study, parametric and semi-parametric approaches such as GLM or GAM have other benefits when compared to ensemble forecasts. The first is that they do not require the computing power or time associated with building an entire suite of models to generate an ensemble, and thus can be considered a much more parsimonious approach to SDM construction. The second is that these approaches lend themselves to interpretation of model structure through the evaluation of model coefficients, partial response curves, and other techniques that facilitate evaluation of parameter effects along ecological gradients. Because ensembles rely solely on model predictions (e.g. mean, median, etc.), they provide little potential for improving ecological inference in this manner.

Our results also highlight the potential issues associated with using complex machine learning algorithms for projecting species distributions into novel temporal domains. Marmion et al. (2009) used a data-partitioning approach to similar to the one used here and found that RF models provided accurate predictions of the withheld data. We found similar results, with very high measures of model accuracy from our internal evaluations. However, we found that RF models performed poorly when evaluated with temporally independent data, providing some of the least accurate predictions (Fig. 2). This result emphasizes the potential issues associated with using only internal model evaluations procedures when developing predictions of future species distributions, namely, that patterns of model accuracy exhibited when using data-partitioning approaches may not accurately reflect patterns of model accuracy when projected into novel temporal domains. However, there is evidence to suggest that ensembles can provide superior accuracy compared to individual algorithms in some situations (Rapacciuolo et al., 2012), suggesting that patterns of accuracy between ensembles and individual algorithms may be context specific. Because the motivation behind many SDM studies is to predict species distributions under future climatic scenarios, we urge caution when using ensemble forecasts and suggest using temporally independent data to validate model projections if the results of such models are to be used to guide conservation planning efforts.

Acknowledgments

Support for this project was provided by the National Science Foundation (award #0819430), the University of California at Davis, the University of Montana, and the US Forest Service. We thank the PRISM group for providing climate data and the many agencies and institutions that have collected the vegetation survey data used here.
